Opioid Abuse in Chronic Pain — Misconceptions and Mitigation Strategies

Nora D. Volkow, M.D., and A. Thomas McLellan, Ph.D.

Chronic pain not caused by cancer is among the most prevalent and debilitating medical conditions but also among the most controversial and complex to manage. The urgency of patients’ needs, the demonstrated effectiveness of opioid analgesics for the management of acute pain, and the limited therapeutic alternatives for chronic pain have combined to produce an overreliance on opioid medications in the United States, with associated alarming increases in diversion, overdose, and addiction. Given the lack of clinical consensus and research-supported guidance, physicians understandably have questions about whether, when, and how to prescribe opioid analgesics for chronic pain without increasing public health risks. Here, we draw on recent research to address common misconceptions regarding the abuse-related risks of opioid analgesics and highlight strategies to minimize those risks.
These misconceptions were drawn directly from questions submitted by physicians to two major websites for pain-management specialists (the American Academy of Pain Management and the American Pain Society).

for that, we suggest recent clinical guidelines. Instead, this review focuses on the pharmacologic properties of opioids that underlie both their therapeutic effects and their abuse-producing effects and on the ways in which these properties should inform us in correcting common clinical misconceptions that interfere with the proper prescription and monitoring of opioids in the management of chronic pain (Table 1).

**Table 1. Misconceptions Regarding Opioids and Addiction.**

<tr>
<td>prescribing of certain types of opioids that may be as risky as types that are</td>
<td></td>
</tr>
<tr>
<td>well known to be associated with addiction. An improved prescribing practice in the management of acute pain is a necessary step in the control of opioid diversion and overdose, since the overprescription of opioids for acute pain is the main source of drug diversion.</td>
<td></td>
</tr>
<tr>
<td><strong>Only patients with certain characteristics are vulnerable to addiction.</strong></td>
<td>Certain conditions do increase the vulnerability to addiction. These include substance-use disorder (including abuse of alcohol, nicotine, and illicit drugs), developmental stage (adolescents are more vulnerable than adults), and certain mental illnesses (e.g., attention deficit–hyperactivity disorder and major depressive disorder). Although some patients are more vulnerable than others, no patient is immune to addiction.</td>
</tr>
<tr>
<td><strong>Medication-assisted therapies are just substitutes for heroin or opioids.</strong></td>
<td>The use of opioid-agonist medications such as methadone and buprenorphine for opioid addiction has led to the misconception that such drugs are just substitutes for the opioid being abused. Although these medications are opioid agonists, their slower brain pharmacokinetics along with their more stable concentrations help to stabilize physiologic processes that are disrupted by intermittent abuse of opioids. The use of these drugs also protects against risks associated with opioid abuse while facilitating recovery.</td>
</tr>

---

Opioid medications exert their analgesic effects predominantly by binding to mu-opioid receptors. Mu-opioid receptors are densely concentrated in brain regions that regulate pain perception (periaqueductal gray, thalamus, cingulate cortex, and insula), including pain-induced emotional responses (amygdala), and in brain reward regions (ventral tegmental area and nucleus accumbens) that underlie the perception of pleasure and well-being. This explains why opioid medications can produce both analgesia and euphoria. Mu-opioid receptors in other brain regions and in peripheral organs account for other common opioid effects. In particular, mu-opioid receptors in the brain stem are mainly responsible for the respiratory depression associated with opioid-overdose incidents and deaths (Fig. 1).

Opioids not only directly activate these brain analgesia and reward regions but also concurrently mediate a learned association between receipt of the drug and the physiological and perceptual effects of the drug — a type of Pavlovian conditioning. Repeated receipt of opioids strengthens these learned associations and over time becomes part of the desire (craving) for the drug’s effects — analgesic or pleasurable. For a patient in chronic pain, even mild levels of pain can trigger the learned associations between pain and drug relief, which are manifested as an urge for relief. Such a conditioned urge for relief from even mild pain can lead to the early, inappropriate use of an opioid outside prescribed scheduling.

Opioid medications vary with respect to their affinity and selectivity for the mu-opioid receptor, since some also bind to kappa- or delta-opioid receptors or to other neurotransmitter receptors and transporters. There is also considerable variation among the drugs with respect to their pharmacokinetics and bioavailability. When combined, these pharmacologic properties affect the rapidity of onset, potency, and duration of both the analgesic and pleasurable effects of opioids.

The effects of opioids — particularly their rewarding effects — are accentuated most when the drugs are delivered rapidly into the brain. This is why diverted opioids that are taken for their rewarding effects are frequently injected. This also explains why the Food and Drug Administration has encouraged and approved abuse-deterrent formulations that are designed to prevent the injection of pharmaceutical opioids (Table 2).
There is lingering misunderstanding among some physicians about the important differences between physical dependence and addiction. The repeated administration of any opioid almost inevitably results in the development of tolerance and physical dependence. These predictable phenomena reflect counter-adaptations in opioid

**Figure 1. Location of Mu-Opioid Receptors.**

Shown are the locations of mu-opioid receptors in the human brain, with high concentration in the thalamus, periaqueductal gray, insula, and anterior cingulate (regions involved with pain perception), in the ventral tegmental area and nucleus accumbens (regions involved with reward), in the amygdala (a region involved with emotional reactivity to pain), and in the brain stem (nuclei that regulate breathing). In the spinal cord, a high concentration of mu-opioid receptors is located in the dorsal horn. Mu-opioid receptors in peripheral terminals modulate the perception of pain, and receptors in the small intestine regulate gut motility.
Table 2. Formulations for Deterrence of Abuse.

When opioids are diverted because of their rewarding effects, they are typically taken at higher doses than were originally prescribed. In other cases, the pills are crushed so that the drug can be snorted, smoked, or injected. These routes of administration result in faster drug delivery into the brain, which in turn is associated with a rapid and more intense drug effect. Thus, strategies for abuse-deterrent formulations have been developed to minimize the likelihood that the opioids will be injected or snorted or taken at higher doses than prescribed.27,28 These strategies include the following:

**Combining the opioid agonist with an antagonist.** Mixing the opioid with naloxone or naltrexone will interfere with the effects if the drug is injected but not if it is taken orally or sublingually. Examples include Embeda (morphine sulfate plus naltrexone hydrochloride) and Targiniq ER (oxycodeone plus naloxone).

**Delivering the opioid in a form that cannot be crushed and extracted.** Examples of such drug-delivery technologies include opioids approved by Food and Drug Administration (FDA) in abuse-deterrent formulations such as Hysingla (hydrocodone) and the new formulation of OxyContin (oxycodeone), as well as opioids not approved as abuse-deterrent formulations, including Exalgo (hydrodromphone), Nucynta ER (tapentadol), Opana ER (oxymorphone), Oxecta (oxycodeone), and Xartemis (oxycodeone and acetaminophen).

**Combining the opioid with a substance that triggers an adverse response.** If the drug is tampered with or used at a higher dose than indicated, such formulations are designed to produce adverse results. Examples include Lomotil (diphenoxylate hydrochloride plus atropine) and Acurox (oxycodeone plus niacin).

**Developing prodrugs that require enzymatic activation.** Such formulations could provide a chemical barrier to in vitro conversion into the active opioid. There are currently no abuse-deterrent formulations approved by the FDA that use this strategy. Examples being developed include prodrugs for hydrocodone, oxycodone, and hydromorphone that require molecular cleavage by trypsin in the digestive system to release the parent opioid.

receptors and their intracellular signaling cascades.29 These short-term results of repeated opioid administration resolve rapidly after discontinuation of the opioid (i.e., in a few days to a few weeks, depending on the duration of exposure, type of opioid, and dose). In contrast, addiction will occur in only a small percentage of patients exposed to opioids. Addiction develops slowly, usually only after months of exposure, but once addiction develops, it is a separate, often chronic medical illness that will typically not remit simply with opioid discontinuation and will carry a high risk of relapse for years without proper treatment. The molecular processes responsible for addiction are also distinct from those underlying tolerance and physical dependence, and so are the clinical consequences.

Tolerance leads to a decrease in opioid potency with repeated administration. Thus, prescribing opioids long-term for their analgesic effects will typically require increasingly higher doses in order to maintain the initial level of analgesia — up to 10 times the original dose.30 Similarly, tolerance with respect to the rewarding effects of opioids leads to the characteristic dose escalation seen in opioid addiction, which can result in daily doses of up to 800 morphine milligram equivalents (MME, the conversion factor used to facilitate comparison of potency among opioids).31

Some opioid effects show tolerance after a single dose,32 whereas for others, tolerance occurs more slowly.29 In particular, tolerance to the analgesic and euphoric effects of opioids develops quickly, whereas tolerance to respiratory depression develops more slowly,33,34 which explains why increases in dose by the prescriber or patient to maintain analgesia (or reward) can markedly increase the risk of overdose.

Physical dependence underlies the physiological adaptations that are responsible for the emergence of withdrawal symptoms on the abrupt discontinuation of opioids. Withdrawal symptoms (e.g., piloerection, chills, insomnia, diarrhea, nausea, vomiting, and muscle aches) vary appreciably in severity (from not noticeable to quite uncomfortable) and duration (1 to 14 days) on the basis of the type, dose, and duration of opioid prescribed.35,36

In the context of chronic pain management, the discontinuation of opioids requires dose tapering in order to prevent the emergence of such withdrawal symptoms. In some patients, the repeated use of opioids can also lead to hyperalgesia, which is a state of heightened pain sensitivity.37,38 In the clinical context, hyperalgesia can lead to inappropriate increases in opioid doses, which further exacerbate rather than ameliorate pain.39 In the case of hyperalgesia, dose tapering or tapering to discontinuation is a better pain-relief strategy.40

Unlike tolerance and physical dependence, addiction is not a predictable result of opioid prescribing. Addiction occurs in only a small percentage of persons who are exposed to opioids — even among those with preexisting vulnerabilities (Table 3). Older medical texts and several versions of the Diagnostic and Statistical Manual of Mental Disorders (DSM) either overemphasized the role of tolerance and physical dependence in the definition of addiction or equated these processes (DSM-III and DSM-IV). However, more recent studies have shown that the molecular mechanisms underlying addiction are distinct
from those responsible for tolerance and physical dependence, in that they evolve much more slowly, last much longer, and disrupt multiple brain processes.\(^{57}\)

Cardinal features of addiction include a pronounced craving for the drug, obsessive thinking about the drug, erosion of inhibitory control over efforts to refrain from drug use, and compulsive drug taking (DSM-5). These behavioral changes in turn are associated with structural and functional changes in the reward, inhibitory, and emotional circuits of the brain.\(^{58,59}\) Clinical studies have also shown that the ability of opioids to produce addiction is genetically modulated, with heritability rates similar to those of diabetes, asthma, and hypertension.\(^{60,61}\) For these reasons, we do not know the total dose or the duration of opioid administration that will reliably produce addiction. However, we do know that the risk of opioid addiction varies substantially among persons, that genetic vulnerability accounts for at least 35 to 40% of the risk associated with addiction,\(^{62-64}\) and that adolescents are at increased risk because of the enhanced neuroplasticity of their brains and their underdeveloped frontal cortex, which is necessary for self-control.\(^{52,62}\) Hence, in adolescents, the risks and benefits of prescribing opioids for pain management need to be even more carefully weighed than in adults.

In a person with an opioid addiction, discontinuation of the opioid will rapidly reverse the tolerance and physical dependence within days or a couple of weeks. In contrast, the underlying changes that are associated with addiction will persist for months and even years after the discontinuation of opioids.\(^{55}\) This finding is clinically relevant, because after abstinence from opioids, addicted patients are particularly vulnerable to overdosing; their intense drive to take the drug persists, but the tolerance that previously protected them from overdosing is no longer present. These effects explain the high risk of overdosing among persons with an opioid addiction after they have been released from prison or from a detoxification program.\(^{66,67}\)

### MITIGATION STRATEGIES

The rewarding effects of opioids play a major role in the risks of opioid diversion, overdose, and addiction. However, the likelihood and severity of these risks are largely independent and governed by different factors. All these risks are present to some degree with all opioids and with all pain diagnoses. This means that no single or simple change in prescribing behavior can be expected to alleviate all risks while properly managing pain. For example, these risks cannot be mitigated simply by restricting prescribing to a particular type of opioid or by avoiding the prescription of opioids to a particular type of patient. However, there are common strategies that can help mitigate all risks, including limiting the prescribed opioid to the lowest effective dose for the shortest effective duration (for both acute and chronic pain) without compromising effective analgesia. Regular monitoring and reassessment provide opportunities to minimize the risks associated with long-term opioid use by allowing for the tapering and discontinuing of opioids among patients who are not receiving a

\(^{\ast}\) The risk of opioid overdose increases in a dose–response manner at opioid doses of more than 20 morphine milligram equivalents (MME).

\(^{\dagger}\) Although addiction is associated with long-term but not short-term opioid use, the prescription of a higher quantity of opioids than is needed for acute pain contributes substantially to the availability of opioids for diversion and abuse.

\(^{\ddagger}\) Sleep-disordered breathing refers to conditions that manifest as abnormal breathing patterns during sleep and includes obstructive sleep apnea and central sleep apnea.

\(^{\S}\) Patients with these disorders are at increased risk because the disposition of various opioid drugs is affected by hepatic and renal impairments, which reduce drug clearance and increase bioavailability.
Screening tools to identify patients with a substance-use disorder. Such tools include the Opioid Risk Tool; the Screener and Opioid Assessment for Patients with Pain (SOAPP), version 1.0; SOAPP-Revised; and the Brief Risk Interview; or the use of a simple question such as “How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?” since patients who score above a certain threshold (e.g., ≥1 to the sample question) may be at increased risk for opioid abuse.

Use of urine drug screening. Such screening, which can be performed before prescription of opioids and periodically as part of regular follow-up, can provide information on drug use not reported by patients and may help in identifying patients who are not taking their prescribed opioids and might be diverting them.

Doctor–patient agreement on adherence. Such personal contracts can help doctors in monitoring a patient’s adherence to prescribed opioid medications.

However, a recent review of the evidence showed that only limited data are available regarding the efficacy of any of these strategies.

PREVENTING DRUG DIVERSION

The most common form of diversion is the transfer of opioid analgesics by patients who have received legitimately prescribed opioids to family members or friends who are usually trying to self-medicate a generic pain. This type of diversion applies to prescriptions given for the management of either chronic or acute pain and would be best managed by educating patients on the dangers of sharing their medications and on the importance of safe storage and disposal.

Approximately 7 to 10% of diversion occurs among patients who feign pain to acquire prescribed opioids, usually with the goal of maintaining their addiction, and who will often attempt to acquire opioids from multiple physicians (doctor shopping). Physicians have attempted to identify dissembling or addicted patients through screening instruments or through detection of so-called aberrant behaviors that are thought to be indicative of addiction (Table 4). However, the most recent review of patient screening efforts showed no evidence that any scale or procedure was effective. Risks of diversion through doctor shopping are best mitigated by the full participation of all prescribers in Prescription Drug Monitoring Programs (PDMPs). PDMPs are statewide electronic databases that collect information on prescription and dispensing of controlled prescription drugs (including opioid drugs) and were designed to monitor information pertaining to suspected abuse or diversion. Although these data have been shown to help health care professionals reduce doctor shopping and overdoses, their use by health care providers is inconsistent. This in part reflects the fact that PDMPs are voluntary programs in many states. Although 25 states and the District of Columbia update their databases daily, as of this writing, only Oklahoma provides real-time reporting. In addition, only 22 of 49 PDMPs share information across states. Another obstacle is that access to PDMP data requires a computer that is separate from that used to access electronic health records. However, implementation and consistent use will be facilitated by rapid changes in laws to require mandatory consultation of a PDMP before prescribing, advances in electronic technologies to deliver PDMP information in real time, better integration of PDMPs with electronic health records, and access of PDMP data across state lines.

REducing risk of overdose

The rate of death from opioid overdose has quadrupled during the past 15 years in the United States. Researchers at the Centers for Disease Control and Prevention have estimated that 28,647 drug overdose deaths (61%) in 2014 in the United States involved some type of opioid, including heroin. Even more prevalent are nonfatal opioid overdoses that require medical care in a hospital or emergency department. Such events have increased by a factor of six in the past 15 years. The contributing factors associated with overdose can be divided into those associated with the opioid itself (type, dose, potency, and duration of action) and those associated with critical features of the patient (Table 3). Although the use of any opioid can lead to overdose, research suggests that exposure to higher doses of all opioids increases the risk of overdose. Opioid doses of more than 100 MME are disproportionately associated with overdose-related hospital
admissions and deaths (Table S1 in the Supplementary Appendix, available with the full text of this article at NEJM.org). The use of long-acting opioids, such as methadone and oxycodone, has also been associated with an increased risk of overdose.

Several identifiable characteristics among patients have been reliably associated with an elevated risk of opioid overdose (Table 3). Included among these factors are a history of overdose, a history of addiction to any substance (but particularly alcohol, benzodiazepines, or opioids), and health problems associated with respiratory depression or concurrent prescription of any medication that has a depressive effect on the respiratory system, such as benzodiazepines and sedative hypnotics. The presence of renal or hepatic dysfunction also increases the risk of overdose, since in patients with either of these conditions, the clearance of many opioid drugs is impaired, which leads to higher and longer-lasting drug levels in blood. Finally, because some cases of overdose may be purposeful suicide attempts, a history of suicidal thoughts or attempts and a diagnosis of major depression are also markers for an elevated risk of overdose.

Recommended mitigation strategies include an overdose risk assessment (Table 3) and urine drug screening before prescription or represcription of opioids (to verify absence of drugs of abuse). The identification of these risks does not automatically rule out opioids as part of effective pain management. However, these risks do indicate the needs for much greater education of the patient (and the patient’s family) about overdose risks, the use of an opioid treatment agreement, increased caution in prescribing high opioid doses or long-acting opioids, more frequent clinical follow-up, and, potentially, a prescription for and instruction in the use of naloxone, an opioid antagonist that can reverse an opioid-induced overdose. Indeed, expanding access to naloxone has been shown to significantly reduce the rate of death from opioid overdoses.

Minimizing the Risk of Addiction

For many years, it was believed that pain protected against the development of addiction to opioid medications. However, epidemiologic studies of opioid addiction among patients in pain, as well as preclinical studies of addiction in animal models of chronic pain, have disproved this belief. Although published estimates of iatrogenic addiction vary substantially from less than 1% to more than 26% of cases, part of this variability is due to confusion in definition. Rates of carefully diagnosed addiction have averaged less than 8% in published studies, whereas rates of misuse, abuse, and addiction-related aberrant behaviors have ranged from 15 to 26%. A small (estimated at 4%) but growing percentage of persons who are addicted to prescription opioids transition to heroin, mainly because heroin is typically cheaper and in some instances easier to obtain than opioids.

Clinical efforts to prevent the emergence of addiction can be initiated in primary care settings. Assessment of addiction risks before opiates are prescribed is recommended as a mitigation strategy (Table 3). Emerging signs of addiction can be identified and managed through regular monitoring, including urine drug testing before every prescription is written, to assess for the presence of other opioids or drugs of abuse. Responsible physicians should be prepared to make a referral for specialty addiction treatment when indicated. Although addiction is a serious chronic condition, recovery is a predictable result of comprehensive, continuing care and monitoring. In particular, the use of medication-assisted therapy in managing opioid addiction among patients with co-occurring pain significantly improves outcomes.

On the basis of research and clinical evidence, the Department of Health and Human Services recently launched an initiative to reduce opioid overdoses and addiction that focuses on improving opioid prescribing practices to reduce opioid-use disorders and overdoses, expanding the use of naloxone to prevent overdoses, and extending the use of medication-assisted treatment to reduce opioid-use disorders and overdoses.

Conclusions

It is no longer possible to simply continue previous practices with respect to the management of chronic pain. The associated risks of opioid diversion, overdose, and addiction demand change. Although there are no simple solutions, we recommend three practice and policy changes that can reduce abuse-related risks and improve the treatment of chronic pain.
Multiple guidelines recommend the use of antidepressant and anticonvulsant medications as either first-line or second-line treatment for neuropathic pain. Evidence of efficacy varies for these strategies, and research is ongoing to assess their value in the management of chronic pain.

Nonopioid analgesics
- Acetaminophen
- Nonselective nonsteroidal antiinflammatory drugs; recommended as first-line pharmacotherapy for osteoarthritis and low back pain in multiple guidelines
- Cyclooxygenase-2 inhibitors
- Anticonvulsants (gabapentin or pregabalin)
- Antidepressants (tricyclics and serotonin and norepinephrine reuptake inhibitors)

Interventional and neural-stimulation therapies
- Epidural injection; may provide short-term improvement for certain pain-associated conditions (e.g., lumbar radiculopathy)
- Brain, spinal cord, and nerve stimulation, including transcranial magnetic stimulation, transcranial direct current stimulation, electrical deep-brain stimulation, and stimulation devices for peripheral nerves or tissues

Biofeedback
- Electromyography to help patients learn to control muscle tension and electroencephalography to help patients learn to influence brain electrical signals in order to modulate pain; may be beneficial in treatment of headaches, some forms of chronic back pain, and other pain disorders
- Neurofeedback with the use of functional magnetic resonance imaging as a supplemental approach for chronic pain management

Evidence of efficacy varies for these strategies, and research is ongoing to assess their value in the management of chronic pain.

Multiple guidelines recommend the use of antidepressant and anticonvulsant medications as either first-line or second-line treatment for neuropathic pain.

INCREASED USE OF SCIENCE-SUPPORTED PRESCRIBING AND MANAGEMENT PRACTICES

The extended prescription of opioids (>8 weeks) for the treatment of chronic pain has questionable benefits for individual patients and presents substantial public health risks. The risks of overdose and addiction from this prescribing practice — both among patients with chronic pain and the public at large — increase with higher doses (>100 MME), longer duration of prescribing, and perhaps the use of long-acting opioids. Despite these facts, a Medicaid study showed that more than 50% of opioid prescriptions were for doses higher than 90 MME and for periods of more than 6 months. Better results can be obtained by using the most contemporary guidelines for pain management.

INCREASED MEDICAL SCHOOL TRAINING ON PAIN AND ADDICTION

Very few medical schools offer adequate training in pain management, and still fewer offer even one course in addiction. The result is that even experienced clinicians are unsure about how to deal with fundamental and omnipresent clinical issues in their practices. Many motivated, well-intentioned physicians do not know whether to prescribe opioids for pain management and, if so, which ones and for how long. Still fewer understand the pharmacologic or clinical relationships among tolerance, physical dependence, and addiction. This education is particularly critical for primary care practitioners, who prescribe more than 70% of opioid analgesics.

INCREASED RESEARCH ON PAIN

At a recent workshop at the National Institutes of Health on the role of opioids in the treatment of chronic pain, attendants recommended several areas of research that are needed for improved clinical practice guidelines. These areas included how to differentiate the unique properties of acute and chronic pain and how to describe the process by which acute pain transitions into chronic pain. Discovery-oriented research was also recommended to identify new, potent non-opioid analgesics and other pain-treatment strategies (Table 5). Access to biomarkers of pain and analgesia that take advantage of neuroimaging technologies or genetic analyses would accelerate the development of new medications and allow for more personalized clinical interventions for pain management.
